

SECTION 5.0
SYNGAS UPGRADING
(Areas 209, 210, 211, 212, 405)

5.1 DESIGN BASIS

- 5.1.1 The syngas upgrading area has three trains, each with one third of the total plant capacity.
- 5.1.2 A saturator is used to adjust the steam/carbon ratio of the raw gas.
- 5.1.3 The shift reactor utilizes high temperature shift catalyst.
- 5.1.4 COS is converted to H₂S to improve sulfur removal.
- 5.1.5 For the purposes of this study, the Selexol process is used to lower the CO₂ and H₂S content to the required levels for methanol synthesis.
- 5.1.6 For the purposes of this study, an Air Resources "LO-CAT" unit is used for recovery of sulfur as molten liquid which is solidified and flaked. Thirty days storage capacity is provided for the flaked sulfur.
- 5.1.7 Two guard beds are provided for final treatment of the sweet synthesis gas. One bed is used to remove trace chlorides, the other bed is used to remove trace sulfur compounds. Each bed is designed for an expected life of three years (minimum).

5.2 PROCESS DESCRIPTION

5.2.1 Raw Gas Compression, Shift and Hydrolysis (Areas 209, 210; Dwgs. 5530-209-Y-001, 210-Y-001)

The clean raw gas from the eight gasifier units is collected in a single header which supplies 3 identical syngas preparation trains. In each train the raw gas is first compressed from 40 psia to 770 psia by a steam turbine driven 3-stage centrifugal compressor.

After compression a portion of the raw gas passes to a saturator vessel where the required steam to dry gas ratio for shift conversion is obtained by direct contact of the gas with hot water. Heat to produce the hot water is obtained by exchange with the hot gas leaving the shift reactor and from condensing crude methanol from the methanol synthesis area. From the saturator the gas passes to the shift reactor where the ratio of hydrogen to carbon monoxide is adjusted to the required level for methanol synthesis by the following reaction in the presence of a sulfur resistant Cobalt-Moly catalyst:

The exit gas from the shift reactor is combined with the remainder of the raw gas and then passes to the COS hydrolysis vessel where the gas is contacted over an alumina hydrogenation catalyst to convert the COS present in the gas to H₂S.

From the COS hydrolysis vessel, the raw gas is cooled by supplying heat to a methanol distillation column reboiler and to a boiler feedwater heater before being sent to the acid gas removal unit.

5.2.2 Acid Gas Removal and Makeup Gas Compression
(Areas 211, 212; Dwgs. 5530-211-Y-001, 212-Y-001)

The "Selexol" acid gas removal unit removes sulfur components in the gas and adjusts the CO₂ level to the required concentration for methanol synthesis.

Removal of the H₂S and CO₂ from the syngas is accomplished in two absorption vessels utilizing dimethylether of polyethylene glycol as a liquid absorbent.

The H₂S is subsequently steam stripped from the absorbent in a stripping tower and sent to the Lo-Cat sulfur recovery unit. The CO₂ is ultimately flashed from the absorbent by pressure let down in a flash drum and then vented to atmosphere, or is recovered for sale.

The sweet syngas from the Selexol unit then passes through two types of guard beds where trace chloride and sulfur compounds are removed by special catalysts. If not removed these compounds would lessen the effectiveness of the downstream methanol synthesis catalysts. Finally the upgraded gas pressure is raised to 1410 psia by the make up gas compressor prior to methanol synthesis.

5.2.3 Sulfur Recovery (Area 405, Dwg. 5530-405-Y-001)

Sulfur recovery is accomplished in an Air Resources LO-CAT unit.

The purge gas stream leaving the H₂S stripper in the "Selexol" acid gas removal area passes to a two stage H₂S absorption system where intimate contact of the gas with a

proprietary circulating liquid is effected. This liquid, consisting of a dilute chelated iron solution, converts the H_2S in the gas into elemental sulfur. The first stage utilizes the slight positive pressure of the gas to achieve a high degree of intimate contact with the circulating solution. This is followed by a packed absorption tower using a very large, open configuration plastic packing.

The spent solution from the absorption tower is pumped to a large aerated vessel where it is regenerated by blowing air into the tank. This re-oxidizes the chelated iron compound so that the solution can be returned to the absorption tower for further sulfur recovery.

Sodium thiosulfate is generated as a by-product which builds up in the recirculating solution and must be removed continuously after the concentration has built up to approximately 25%. Some catalyst is lost with this bleed stream and must be replaced with fresh catalyst.

The elemental sulfur formed in the absorbers is settled as a dilute slurry in the bottom of the oxidizer vessel and pumped through a heat exchanger train to a molten sulfur separator. Molten sulfur is withdrawn from the bottom of the separator vessel, solidified, flaked, and sent to storage. Clarified slurry returns to the process. The sulfur will be available for sale or disposal.

5.3 ENGINEERING DESIGN DATA

Design data pertinent to syngas upgrading is detailed in the Process Flow Diagrams immediately following this page, in the Equipment List beginning on page 5/6, and in the Drawings following page 5/21.
